Abstract. We demonstrate a compact, open-path, quantum cascade-laser-based atmospheric ammonia sensor operating at 9.06 µm for high-sensitivity, high temporal resolution, ground-based measurements. Atmospheric ammonia (NH\textsubscript{3}) is a gas-phase precursor to fine particulate matter, with implications for air quality and climate change. Currently, NH\textsubscript{3} sensing challenges have led to a lack of widespread in situ measurements. Our open-path sensor configuration minimizes sampling artifacts associated with NH\textsubscript{3} surface adsorption onto inlet tubing and reduced pressure sampling cells, as well as condensed-phase partitioning ambiguities. Multi-harmonic wavelength modulation spectroscopy allows for selective and sensitive detection of atmospheric pressure-broadened absorption features. An in-line ethylene reference cell provides real-time calibration (±20 % accuracy) and normalization for instrument drift under rapidly changing field conditions. The sensor has a sensitivity and noise-equivalent limit (1σ) of 0.15 ppbv NH\textsubscript{3} at 10 Hz, a mass of ∼5 kg and consumes ∼50 W of electrical power. The total uncertainty in NH\textsubscript{3} measurements is 0.20 ppbv NH\textsubscript{3} ± 10 %, based on a spectroscopic calibration method. Field performance of this open-path NH\textsubscript{3} sensor is demonstrated, with 10 Hz time resolution and a large dynamic response for in situ NH\textsubscript{3} measurements. This sensor provides the capabilities for improved in situ gas-phase NH\textsubscript{3} sensing relevant for emission source characterization and flux measurements.

1 Introduction

Atmospheric ammonia (NH\textsubscript{3}), the third most abundant nitrogen species and dominant atmospheric base, is an important precursor to ammoniated fine particulate matter (Nowak et al., 2007; Pinder et al., 2008). Total NH\textsubscript{x}, the sum of gas-phase NH\textsubscript{3} and particulate ammonium (NH\textsubscript{4}\textsuperscript{+}), is an increasingly important component of the reactive nitrogen budget, with implications for human and ecosystem health (Galloway et al., 2003; Pinder et al., 2008; Bobbink et al., 2010). Ammoniated aerosols are a dominant component of inorganic aerosol mass in both clean and urban regions (Jimenez et al., 2009). Gas-phase NH\textsubscript{3} measurements are crucial for understanding aerosol nucleation and new particle formation (Ball et al., 1999; Hanson and Eisele, 2002; McMurry et al., 2005; Benson et al., 2011), which facilitate long-range transport of aerosol ammonium and nitrate (Nowak et al., 2007; Pinder et al., 2008). Ammoniated sulfate aerosols also play an important role in cirrus cloud nucleation (Tabazadeh and Toon, 1998; Wang et al., 2008), and aerosol–cloud interactions have significant yet highly uncertain radiative effects on climate (Adams et al., 2001; Martin et al., 2004; Solomon et al., 2007).

Anthropogenic NH\textsubscript{3} emissions have more than doubled since preindustrial times, largely due to agricultural livestock and fertilizer emissions (Galloway et al., 2003; Battye et al., 2003; Anderson et al., 2003; Aneja et al., 2008). Uncertainties as large as 50 % exist in global NH\textsubscript{3} emission budgets due to the spatial and temporal variability of emissions and a lack of in situ measurements for emission inventory validations (Battye et al., 2003; Clarisse et al., 2009). Recent
comparisons between measured emissions and concentrations with model inventories found significant discrepancies (Heald et al., 2012; Nowak et al., 2012; Walker et al., 2012).

Gas-phase NH$_3$ has a short atmospheric lifetime of a few hours to a few days, which depends on ambient temperature, relative humidity and aerosol composition (Anderson et al., 2003). High spatial and temporal resolution observations are needed to fully characterize NH$_3$ dynamics, including aerosol nucleation, gas-phase uptake onto particles and volatilization of particulate ammonium (Battye et al., 2003; Nowak et al., 2007; Pinder et al., 2008). In situ NH$_3$ instruments require high (sub-ppbv) sensitivity to measure low atmospheric mole fractions (pptv–ppbv), fast response time and a large dynamic range to capture atmospheric variability (von Bobrutzki et al., 2010). Ammonia sensors must also account for gas-phase NH$_3$ surface adsorption effects and condensed-phase partitioning due to changes in temperature and relative humidity between the sampling volume and ambient atmosphere (Yokelson et al., 2003).

To date, the NH$_3$ measurement challenges have resulted in a variety of different approaches. Conventional offline NH$_3$ sensors (passive filters, denuders and ion chromatography) often have sufficient sensitivity (< 1 ppbv NH$_3$), but have long integration times, lack the requisite selectivity and are labor intensive to analyze (Fehsenfeld et al., 2002; von Bobrutzki et al., 2010; Ellis et al., 2011). Chemical ionization mass spectrometry (CIMS) NH$_3$ instruments have high time resolution (seconds), selectivity and extremely high sensitivity (< 100 pptv NH$_3$), but require large power consumption (kW) and space (multiple instrument racks) (Nowak et al., 2007; Benson et al., 2010; Sintemann et al., 2011). Laser absorption spectrometers for gas-phase NH$_3$ have been developed for real-time, high-sensitivity and selective detection. Near-infrared diode lasers have been used for NH$_3$ detection, but their sensitivity is limited due to the NH$_3$ overtone bands in the near infrared (Claps et al., 2001; Kosterev and Tittel, 2004).

More recently, advances in room temperature, distributed-feedback quantum cascade (QC) lasers have led to the development of QC-laser-based NH$_3$ sensors using the strongest NH$_3$ absorption transitions located in the mid-infrared spectral region (Manne et al., 2006; Whitehead et al., 2007; McManus et al., 2008; Manne et al., 2009; Curl et al., 2010; Ellis et al., 2010; Gong et al., 2011). Although these closed-path systems are highly sensitive (ppbv or sub-ppbv), they suffer from sampling artifacts that limit precision and response time and complicate calibration methods (Whitehead et al., 2008; von Bobrutzki et al., 2010). In addition, these systems are large (usually > 100 kg) and require pumps and temperature control systems with high power consumption (usually hundreds of watts).

In contrast to these closed-path systems, nonintrusive open-path designs address the sampling challenges and provide fast response times (Zondlo et al., 2010; McDermitt et al., 2011; Tao et al., 2012b). Peeters et al. (2000) demonstrated laboratory performance of an open-path cavity-enhanced absorption spectrometer for NH$_3$, but the detection limit was not sufficient for atmospheric measurements. Open-path remote systems employing Fourier transform infrared (FTIR) spectroscopy techniques have been demonstrated for path-integrated field NH$_3$ measurements, including agricultural flux measurements with single ppbv sensitivity (Griffith and Galle, 2000; Galle et al., 2000). Open-path tunable diode laser absorption spectroscopy (TDLAS) and differential optical absorption spectroscopy (DOAS) systems in remote measurement configurations have been used to measure NH$_3$ with ppbv detection limits (Thoma et al., 2005; Volten et al., 2012). Mount et al. (2002) demonstrated open-path NH$_3$ measurements with a mid-ultraviolet DOAS system and achieved 1 ppbv NH$_3$ sensitivity in 1 s. The high time resolution (> 1 Hz) of this approach illustrated the value of an open-path configuration. However, all of these sensors require long paths rather than compact sensor footprints. Currently, there are significant hurdles for compact, open-path, laser-based NH$_3$ sensing, including pressure-broadened absorption lineshapes sensitive to changes in environmental temperature and pressure and interferences from broad, overlapping absorption features from other atmospheric species.

To address the limitations of closed-path techniques and challenges for compact, open-path sensing, we demonstrate the performance of a compact, open-path, high-sensitivity, QC-laser-based atmospheric NH$_3$ sensor. The sensor probes the fundamental mid-infrared NH$_3$ absorption transitions using a QC laser at 9.06 µm. Multi-harmonic wavelength modulation spectroscopy is used to isolate overlapping absorption features, and an in-line ethylene reference cell is used for online calibration and normalization to account for sensor drift. The system is relatively compact, low power (~ 50 W), and low mass (~ 5 kg), with a 10 Hz time resolution and high sensitivity (0.30 ppbv minimum detection limit at 10 Hz). The fast response time and dynamic range capabilities of the open-path system are illustrated. In situ NH$_3$ measurements of emission sources are highlighted.

2 Instrument design

2.1 Sensor setup

The open-path, QC-laser-based NH$_3$ sensor is shown schematically in Fig. 1. Overall, the open-path design is optimized for field portability with a 100 cm × 10 cm × 11 cm sensor head and a 35 cm × 33 cm × 15 cm drive electronics unit. The total sensor head mass is 5 kg including basic shielding (not shown in Fig. 1) to protect components in field conditions. The sensor uses a thermo-electrically cooled, continuous-wave, single-mode, 9.06 µm quantum cascade laser (Alpes Lasers) in a high heat load package, which is detected by a three-stage, TE-cooled,
infrared HgCdTe photodetector (Judson Teledyne). The opto-mechanical design consists of the laser, collimating lens, in-line ethylene reference cell, steering mirrors, multi-pass optical cell and detector. A Herriott multi-pass cell with spherical mirrors (Herriott et al., 1964) is used to achieve path lengths of 30–60 m in a 70 cm base path, depending on the spot pattern implemented. The laser beam is directed into the optical cell consisting of two protected silver-coated, 3-inch-diameter spherical mirrors, both with a 6 mm-diameter hole for laser beam entry and exit. We use a configuration with laser and detector components on opposite sides of the optical cell for practical opto-mechanical component design considerations. The QC laser beam size is optimized with focusing mirrors to minimize clipping and distortion effects as the laser beam enters the input hole. A visible alignment laser (HeNe) is used to image the optical spot pattern on the mirrors and couple the QC laser beam into the optical cell. Custom anti-reflection coatings (reflectivity < 0.5 %) are applied to all transmissive optics, including laser and detector housing windows, to minimize signal baseline artifacts due to interference fringes that are unstable with ambient temperature changes.

The QC laser is driven by a low-noise current driver (Wavelength Electronics, QCL500) and thermally controlled with a precise temperature controller (Wavelength Electronics, HTC3000). The QC laser current is modulated with a sawtooth ramp (50 Hz) and higher-frequency (15 kHz) sinusoidal modulation. The QC laser tuning range for NH₃ measurements is 0.52 cm⁻¹, based on the current tuning rate at 50 Hz ramp frequency. Tao et al. (2012a) demonstrated that for the QC laser used here, the current tuning rate decreases with increasing ramp or modulation frequency. Although higher ramp and modulation frequencies should improve sensitivity by minimizing laser excess noise, the decrease in tuning rate at higher frequencies, the broad spectral features probed, and practical QC laser tuning rate limitations prevent us from going to higher frequencies. The tuning rate limitations allow us to achieve a modulation index of ∼1.4 for NH₃ measurements, which is not at the most sensitive, optimal value of 2.2 (Reid and Labrie, 1981).

The detector signal is acquired with a National Instruments data acquisition board (NI-USB 6251) and processed in real time. The 50 Hz raw signal is co-averaged to 2–10 Hz, depending on the field conditions and signal-to-noise ratio (SNR). Multi-harmonic wavelength modulation spectroscopy (WMS) detection is performed with a custom LabVIEW software algorithm, eliminating the need for a benchmark lock-in amplifier, as described in Tao et al. (2012b). The open-path configuration eliminates the need for large pumps that require high power consumption, resulting in significantly lower power consumption (~50 W) than existing closed-path NH₃ sensors. The laptop computer power consumption (currently ~50 W) can be reduced further with alternative, lower-power single-board computers or embedded systems. The system requires no cryogenic cooling, allowing for autonomous field operation.

### 2.2 Spectroscopy

The strongest NH₃ absorption transitions occur in the mid-infrared spectral region near 10.3 µm and are probed by other QC laser absorption spectrometers (McManus et al., 2008; Gong et al., 2011). However, this spectral region is not optimal for open-path detection, due to the carbon dioxide (CO₂) and water vapor (H₂O) pressure-broadened absorption lines that overlap with the NH₃ absorption lines. The most optimal absorption feature for open-path NH₃ detection is at 9.06 µm, a region between the strong absorption bands of N₂O below 8.9 µm and absorption bands of CO₂ and O₃ above 9.1 µm. The selected absorption feature is ~50 % weaker than the stronger NH₃ features near 9.5 µm, but the spectral clarity at 9.06 µm allows for higher sensitivity. Figure 2a shows spectra simulated using the HIgh-resolution TRANsmission Molecular Absorption database (HITRAN) in the 9.06 µm region for 1 ppbv NH₃ and typical ambient mixing ratios of atmospheric absorbers at 296 K and 1013.25 hPa for a 60 m optical path length. The NH₃ absorption feature at 9.06 µm in Fig. 2a is a superposition of six overlapping absorption transitions. This feature overlaps with the minimum of a neighboring H₂O absorption feature, producing a direct absorption baseline. Owen et al. (2013) performed spectroscopic studies on relevant atmospheric absorbers in this region at reduced pressure to characterize the interferences. For open-path detection at ambient pressures, wavelength modulation spectroscopy is a well-suited detection technique for spectral resolution of these weak, overlapping absorption features (Schilt et al., 2003; Zondlo et al., 2010). As shown in Fig. 2b,
second harmonic (2f) detection minimizes the water vapor baseline and improves sensitivity and selectivity (Reid and Labrie, 1981). Other atmospheric species such as CO₂, O₃ and SO₂ also absorb in this region below ~5 × 10⁻⁵ fractional absorption. We note that polluted conditions are illustrated in Fig. 2 (5 ppbv SO₂ and 80 ppbv O₃) to represent ambient conditions with possible interferences. However, the NH₃ absorption at 9.06 µm for 1 ppbv NH₃ is greater than five times the absorption of these species in this spectral region. Overall, the only significant interfering species for 2f detection at 9.06 µm is H₂O, which is addressed in the following section. The O₃ absorption baseline begins to interfere significantly for NH₃ mole fractions below 100 pptv.

2.3 Ammonia mole fraction retrieval

The ammonia mole fraction is retrieved with real-time spectral fitting at 10 Hz. We simulate the direct absorption signal recorded by the detector with multiple Voigt lineshape profiles for all relevant absorption transitions within the laser scan range as follows:

\[ D = \chi \cdot I(t) \cdot \exp(-\sum_i (x_i S_i L_i \psi_i(T, P, \nu(t)))) \]

where \( \chi \) is the detector collection efficiency; \( I(t) \) is the laser intensity function; \( x_i, S_i \) and \( L_i \) are the number density, absorption line strength and path length, respectively, for different absorbing species \( i \); and \( \psi_i(T,P,\nu(t)) \) is the Voigt lineshape function for absorption feature \( i \), a function of temperature, pressure and wavenumber \( \nu(t) \). This signal is multiplied by a reference signal at the \( r \)th harmonic and passed through a virtual lock-in amplifier based on a numerical wavelength modulation spectroscopy model (Tao et al., 2012b). A least-squares fitting routine is implemented to produce fitting coefficients for mole fraction, DC signal offset, linear and second-order polynomial baselines. The second-order polynomial baseline fitting accounts for baseline effects, including detector nonlinearity, intensity modulation and interference fringing. The spectroscopic parameters used in the fitting routine for the NH₃ absorption lines of interest have been measured experimentally by Sun et al. (2013), and generally agree to within 10 % of HITRAN. Ambient temperature and pressure are measured with a digital temperature sensor (HYT 271, ±0.2 °C accuracy) and digital pressure sensor (MS5803-01BA, ±0.5 hPa accuracy) at 1 Hz and updated in real time for the fitting routine. An in-line ethylene reference cell is inserted into the optical path as explained below.

Water vapor introduces multiple, minor potential interferences for the 2f NH₃ retrieval. The average ambient H₂O mixing ratio for a given region and time period of sensor field deployment is used for spectral fitting of the H₂O absorption baseline and used to calculate absorption line widths to account for H₂O broadening using the coefficients measured by Owen et al. (2013). On short timescales, the variability of ambient H₂O vapor (a few hundred ppmv) has a negligible (<0.5 %) impact on the 2f NH₃ retrieval. For larger changes of water vapor, the H₂O mixing ratio is updated in the spectral fit using routine meteorological data.

The NH₃ and ethylene absorption features (centered at 1103.46 cm⁻¹ and 1103.36 cm⁻¹, respectively) are fit simultaneously both in second (2f) and eighth (8f) harmonics. The multi-harmonic approach separates the overlapping, broad ambient NH₃ absorption feature from the narrower ethylene reference signal as demonstrated by Sun et al. (2013). Figure 3 shows representative 2f and 8f spectra along with fitting results and residuals for a 19.0 ppbv ambient NH₃ signal. The 2f signal has two extra troughs, indicated by arrows, due to the ethylene absorption overlapped with the ambient
Fig. 3. Ammonia 2f (left) and ethylene 8f (right) spectra recorded at 10 Hz with real-time fitting results (dotted lines) and residuals. The 2f NH$_3$ signal was recorded for ambient laboratory conditions of 19.0 ppbv NH$_3$. The two arrows in the 2f plot denote the locations of the two extra troughs due to the ethylene reference signal.

NH$_3$ signal. The eighth harmonic (8f) is used for ethylene reference signal detection to achieve optimal separation between ambient NH$_3$ and ethylene reference signals. The 8f signal isolates the relatively narrow, reduced pressure ethylene reference signal, with negligible influence from ambient NH$_3$ absorption at 8f. We do not use harmonic orders higher than 8f due to limits of signal-to-noise ratio, since the signal intensity decreases as harmonic order increases. The even harmonic orders are advantageous since the maximum of the WMS function occurs at the spectral line center, which is useful for line-locking procedures.

2.4 Calibration methods

We implement an online spectroscopic calibration method using ethylene, which exhibits negligible adsorption artifacts compared with NH$_3$. We do not use an NH$_3$ reference calibration cell due to adsorption artifacts associated with changes in cell temperature and pressure. In addition, when ambient and reference absorption features of the same species are overlapping, separating changes in mole fraction from changes in the reference signal becomes difficult. The in-line ethylene reference cell contains 1.5 % ethylene in nitrogen at 50 hPa total pressure in a 3 cm length. The ethylene mixing ratio was chosen to be comparable to NH$_3$ signals at ppbv levels. Spectroscopic parameters of both NH$_3$ and ethylene absorption features have been measured and compared with the HITRAN database to evaluate the calibration accuracy. Sun et al. (2013) has demonstrated this ethylene signal can serve as a reference of NH$_3$ mole fraction in real time, with an overall calibration accuracy of ±20 %.

We also perform offline absolute calibration using NH$_3$ direct absorption measurements. Prior verification of path length was performed and uncertainties in the HITRAN parameters for these NH$_3$ absorption lines were previously characterized (Sun et al., 2013). Owen et al. (2013) also studied these absorption transitions and reported lineshape parameter uncertainties of <10 %. The standard NH$_3$ mole fractions for calibration of our WMS retrieval are calculated based on a direct absorption fitting using these calibrated HITRAN parameters. The absolute accuracy of this offline calibration method (±10 %) is comparable to current high-sensitivity, state-of-the-art NH$_3$ sensors. For example, the pulsed QC-laser-based NH$_3$ instrument demonstrated by McManus et al. (2008) has a typical concentration uncertainty of 5–20 %. Nowak et al. (2007) found uncertainties in CIMS NH$_3$ measurements to be ±25–30 % during field operation. Sintermann et al. (2011) found calibration accuracy of ~5 % for a CIMS NH$_3$ instrument.

In addition to calibration, the in-line ethylene reference signal is especially advantageous as it provides normalization for sources of instrument drift. Normalization for sensor drift is essential for open-path systems exposed directly to changing environmental conditions, which lead to undesirable or unknown opto-mechanical and electronic responses such as optical interference fringes, electrical component drift, laser and detector instabilities and light attenuation due to precipitation. In addition, the sharp peaks and troughs of the 8f signal are used for line-locking via laser current adjustment to account for thermal drifts of the laser wavelength. This improves the drift during a typical ~10 °C diurnal ambient temperature cycle from 0.04 cm$^{-1}$ to <0.005 cm$^{-1}$.

3 Instrument performance

3.1 Calibration

We perform absolute calibration offline using direct absorption spectroscopy as a reference method to measure NH$_3$ mole fraction independent of our WMS NH$_3$ retrieval based on 2f detection. The open-path optical cell is enclosed in a polyethylene calibration tube, into which a flow of 25 ppmv NH$_3$ in N$_2$ is introduced. This 25 ppmv NH$_3$ standard mixing ratio is decreased incrementally by dilution with dry air and each calibration point is recorded in both 2f and direct absorption as shown in Fig. 4. The horizontal axis is the NH$_3$ standard mole fraction derived from direct absorption measurements. The vertical axis displays the retrieved NH$_3$ mole fraction based on 2f spectral fitting with the online spectroscopic calibration method described in Sect. 2.3. We note that the calibration is performed at mole fractions much less than that of the original 25 ppmv NH$_3$ standard. Therefore, we use HITRAN parameters appropriate for NH$_3$ in dry air. The mole fraction retrieval is derived from nonlinear Voigt lineshape fitting of the direct absorption spectra along with measured ambient temperature and pressure, and assumes the mole fraction is linearly proportional to the fractional absorption for typical (ppbv) atmospheric NH$_3$ mole fractions. However, the retrieved mole fraction does not scale linearly with the standard mole fraction due to strong absorption non-linearity at mole fractions >100 ppbv NH$_3$. Therefore, we fit a third-order polynomial to calibrate the retrieved mole fraction as shown in Fig. 4. The linearity of retrieved mole
fraction is shown in the inset plot of Fig. 4 for mole fractions below \( \sim 120 \) ppbv NH\(_3\). In this regime, we can assume absorption is linear with number concentration (and mole fraction assuming constant temperature and pressure) based on the Beer–Lambert law weak absorption limit. A linear best-fit line in this range yields \( R^2 = 0.99 \), in agreement with the weak absorption limit. The surface adsorption and partitioning artifacts associated with NH\(_3\) calibrations present unique challenges which limit accuracy, especially for low ambient mole fractions. Our accuracy is constrained by the uncertainty in the HITRAN parameters for the NH\(_3\) absorption features, which is estimated to be \( \sim 10\% \) (Sun et al., 2013).

Calibration of the zero NH\(_3\) baseline offset is also important when retrieving NH\(_3\) mole fractions near the detection limit. The zero calibration point is obtained by flushing the calibration tube with dry air and coating the calibration tube surfaces with a concentrated (\( \sim 20\text{wt}\%\)) citric acid solution to minimize NH\(_3\) desorption effects. We note that true zero NH\(_3\) conditions are very difficult to achieve for any NH\(_3\) instrument, due to surface adsorption and partitioning artifacts as well as residual NH\(_3\) found in dry air. We perform zero calibrations prior to, during, and following field deployments, along with the full calibration procedure described in Sect. 2.4. Based on these zero calibrations, our absolute uncertainty in the zero calibration is 0.20 ppbv NH\(_3\). It is important to note that each time zero calibration is performed, there is additional uncertainty due to differences in the amount of residual NH\(_3\) in the calibration tube. Thus, 0.20 ppbv is an upper limit to our estimate of the zero calibration uncertainty. This metric defines an absolute accuracy at low NH\(_3\) mole fractions, due to uncertainty in the zero calibration point. Thus, the total estimated uncertainty is 0.20 ppbv NH\(_3\) ± 10 %.

To investigate precision and stability of the open-path NH\(_3\) sensor, Allan deviation analyses (Werle et al., 1993) are performed on NH\(_3\) and ethylene reference signal time series. We compare the drift characteristics of the ambient and reference signals to determine the optimal integration time for normalization by the ethylene reference signal. For this analysis, we normalize both NH\(_3\) and ethylene retrievals by the 1f DC value to account for changes in light intensity on the detector. The NH\(_3\) mole fraction and air temperature are variable in the laboratory during the recorded time series, whereas the ethylene mixing ratio in the reference cell is essentially constant.

Figure 5 shows the Allan deviation plot for NH\(_3\) measurements, with a mean mixing ratio of 14.6 ppbv NH\(_3\) recorded in the laboratory at 10 Hz time resolution. The precision is \( \sim 1\% \), or 0.15 ppbv NH\(_3\), at 10 Hz. The precision is similar at 1 Hz integration time. The minimum precision is \( \sim 15\) pptv NH\(_3\) for an integration time of \( \sim 200\) s, beyond which drift dominates the Allan deviation. The 10 Hz precision is maintained out to timescales greater than 1 h. We note that while the 2f NH\(_3\) signal is fit in real time at 10 Hz, the data acquisition is synchronized by the 1 Hz GPS pulse-per-second signal and the current linelocking scheme also at 1 Hz, which results in a transition from 100 % to an effective 10 % duty cycle from 0.1 s to 1 s integration time. We also note that the corresponding offset is consistent with a \( \sqrt{10} \) decrease in Allan deviation resulting from a 10 % duty cycle (Werle et al., 1993) at 1 Hz and longer timescales.

The Allan deviation plot for the ethylene reference signal recorded at 1 Hz time resolution is shown in Fig. 6. Ethylene signals are co-averaged to 1 Hz time resolution to improve the signal-to-noise ratio at the higher (8f) harmonics. The precision of the ethylene signal is \( \sim 1\% \) at 1 Hz, comparable...
4.5 h time series. The Allan deviation is expressed as a percent of the mean value of the reference signal time series (relative Allan deviation). Ethylene is recorded at 1 Hz time resolution.

The precision improves as integration time increases, but interference fringing at the higher harmonics (8f) and laser thermal drift limit this improvement for integration times > 100 s. The minimum of the NH$_3$ Allan deviation in Fig. 6 occurs at an integration time of ~ 200 s. Thus, a 200 s integration time is optimal for normalization by the ethylene reference signal to account for drift in the NH$_3$ signal. Note that the data in Figs. 5 and 6 show drift of ~ 1% or less at 3000 s integration time, which is much lower than the overall accuracy (±10%). In this case, the in-line ethylene reference signal is of marginal value under relatively constant laboratory conditions. However, the in-line ethylene signal is an important method to account for much larger system drifts expected under rapidly changing field conditions and over longer timescales (days).

3.3 Minimum detection limit

The minimum detection limit of the NH$_3$ sensor was determined by the measuring 2 σ of the background zero ammonia signal time series. The short-term noise is expected to be the limiting factor for the minimum detection limit, as the Allan deviation plot shown in Fig. 5 indicates precision better than the 10 Hz precision on long timescales.

We analyze the spectral fitting at 1 ppbv NH$_3$ mole fraction with baseline subtraction to estimate the spectral noise levels. Figure 7a shows a 1.0 ppbv NH$_3$ signal with spectral fitting and residuals. Figure 7b illustrates the base functions for the full spectral fit in Fig. 7a, with contributions from NH$_3$, ethylene and the polynomial baseline. Based on the height of the baseline-subtracted 2f NH$_3$ signal and the residuals of the fit to this baseline-subtracted signal, the SNR for this spectrum is ~ 7.6, corresponding to a spectral noise level (2σ) of 0.26 ppbv NH$_3$ at 1 Hz. The interference due to O$_3$ and CO$_2$ absorption lines is ~ 20% of the 1 ppbv NH$_3$ signal (see Sect. 2.2), which is smaller than the baseline spectral noise (~ 26%). We note that this estimate is derived from only one spectrum and may not be representative of the temporal variability of the background noise, which is expected to be dominated by optical interference fringing and electronic noise.

Background concentrations are difficult to determine for NH$_3$ in an open-path configuration, in large part due to the need to enclose the sensor, leading to adsorption and desorption effects with typical laboratory mole fractions greater than 10 ppbv NH$_3$. To achieve a zero NH$_3$ background signal and examine the time series characteristics of the noise and spectral fitting, we conducted additional experiments inside a pressure-regulated chamber. The calibration tube and the entire sensor head were placed inside a larger chamber with its inside walls coated with the citric acid solution. The larger chamber was pumped to a reduced pressure of 100 hPa. Even though the sensor was at 100 hPa, we maintained the same modulation amplitude as at ambient pressures. The absorption features of NH$_3$ and other relevant species are therefore overmodulated (effective modulation index > 5 for NH$_3$ at 100 hPa), effectively broadening and decreasing the 2f signal height by 67% compared to ambient pressures. The overmodulated 2f NH$_3$ signal is used to calculate the background noise, since it minimizes the influences of residual NH$_3$ on the 2f signal. We also verified that there was negligible residual NH$_3$ in the chamber by switching to lower modulation amplitude appropriate for 100 hPa. Figure 8 shows the 2f spectrum recorded at 100 hPa under these conditions, which is effectively representative of etalon and electrical noise. It is assumed here that etalons, determined by the free spectral range of various transmissive optics, are not affected by pressure changes since the whole sensing system is enclosed inside the chamber. We fit the background signals to
the ambient pressure lineshape function to examine how the spectral fit to the background (which should nominally be zero) changes over time. The noise-equivalent limit, defined as 1σ of the background signal time series, is 0.15 ppbv NH₃ at 10 Hz and the minimum detection limit (2σ) is 0.30 ppbv NH₃ at 10 Hz. This detection limit is also consistent with the measurement precision shown in Sect. 3.2 and the spectral noise analysis described above.

We note that other potential methods to achieve background measurements have limitations for our system. One approach would be tuning the laser to a different wavelength region. However, the QC laser used here has a limited tuning range and this method will produce a different baseline due to changes in laser optical power, detector response and interference fringing. In addition, there are other absorbing species (e.g., H₂O, CO₂, O₃, SO₂) that will contribute to the spectroscopic baseline on either side of the NH₃ spectral feature of interest.

### 3.4 Open-path time response

We demonstrate the dynamic response of the open-path configuration. Figure 9 shows the time series of NH₃ mixing ratios measured in the field on a mobile vehicular platform at a dairy farm over the course of ~3 min at 5 Hz time resolution. During this time series, an order-of-magnitude decrease in mixing ratio from ~2.0 ppmv NH₃ to 200 ppbv NH₃ is observed within 1 s. The inset plot of Fig. 9 shows a 5 s portion of this time series on a logarithmic y scale to emphasize the two-order-of-magnitude change in mixing ratio. During this time period, the sensor records an increase from ~200 to ~900 ppbv NH₃ in 1 s followed by a decrease in mixing ratio (~900 to ~200 ppbv NH₃) in 0.8 s. The mixing ratio decreases by two orders of magnitude to background levels (~10 ppbv NH₃) within 2 s following the ppmv maximum as the sensor left the farm and was no longer sampling the emission plume. This demonstrates the fast response time of the open-path sensor for two-order-of-magnitude changes in mixing ratio in a very short (2 s) time period.

We also demonstrate the time response for smaller mixing ratio enhancements. Figure 10 shows a time series of mobile measurements on the highway recorded at 2 Hz time resolution. There are two enhancements observed due to vehicle traffic emissions on the highway. For the first spike at 15:45:40 local time, the sensor recorded an increase of 10 ppbv NH₃ (13.0 to 23.0 ppbv) in 1 s. For the second maximum at 15:49:30 local time, the decrease in mixing ratio from 16.0 to 10.0 ppbv following the transient spike is also recorded in 1 s. These measurements demonstrate similar fast response for a lower range of mixing ratios.

Ammonia surface adsorption and desorption effects in closed-path sensors typically limit the response time (for several hundred ppbv NH₃ changes) to a few seconds, resulting in attenuation of high-frequency concentration fluctuations (Yokelson et al., 2003; Nowak et al., 2007; McManus et al., 2008; Whitehead et al., 2008; Ellis et al., 2010; Gong et al., 2011). The time response of closed-path sensors is often defined by the initial time constant for gas exchange and the slower surface adsorption time constant (e.g., ~0.4 s and ~15 s, respectively, for a QC-TDLAS instrument) (Ellis et al., 2010). For long-term stationary monitoring applications, this time response is sufficient since data are averaged to minutes or longer timescales. However, for mobile platform measurements of transient emissions with order-of-magnitude changes in mixing ratios, as well as eddy covariance flux measurements, a time response of at least 1 Hz, as demonstrated for this open-path sensor, is critical.
4 Field measurements

The open-path NH$_3$ sensor has been field deployed in a wide range of environments with autonomous operation on daily timescales. These include hot, dusty, and dry conditions in the San Joaquin Valley, California; > 40 °C ambient temperatures and high humidity (mid-20 °C dew points) in Princeton, New Jersey; and cold, rain and dew conditions in Baltimore and Beltsville, Maryland (Miller et al., 2012). The sensor has also operated on a mobile, battery-powered vehicular platform for > 7000 km, in which ambient air flows across the optical cell region as the vehicle moves and the sensor platform is exposed to vibrations. These field deployments led to improvements in the opto-mechanical design to address temperature cycling effects on the alignment, laser thermal stability and detector temperature control (Miller et al., 2012). The optical cell structure and mirror mounting were custom designed with carbon fiber rods to minimize temperature cycling effects.

We performed high time resolution (5 Hz) open-path NH$_3$, mobile measurements on the road and at a local animal farm (pigs, turkeys) in central New Jersey to measure vehicular and agricultural emissions. All field NH$_3$ measurements are corrected for water vapor dilution and expressed as mixing ratios in dry air. Simultaneous measurements of a vehicle emission tracer carbon monoxide (CO) by a separate QC-laser-based sensor (Tao et al., 2012b) were used to identify these emission sources. Figure 11a shows the time series of NH$_3$ measurements at the animal farm. High mixing ratios above 1 ppmv NH$_3$ are observed and do not correlate with CO, which remained at near background mixing ratio at the animal farm. Figure 11b illustrates on-road vehicle NH$_3$ emission measurements, with maximum mixing ratios of ~60–120 ppbv NH$_3$, depending on vehicle type and driving conditions. The enhancements in NH$_3$ mixing ratio (Fig. 11b) correlate with on-road CO measurements. These time series demonstrate the open-path NH$_3$ sensor is capable of performing high time resolution field measurements to capture various emission sources.

The field measurements of NH$_3$ and the nonadsorbing gas CO shown in Fig. 11b illustrate that there is no delay between the spikes of these two species, which occur on timescales of seconds, due to vehicle exhaust emissions. Other field measurements performed in tunnels (not shown here) indicate that open-path measurements of nonadsorbing gases, such as CO$_2$, can serve as an indicator of true mixing ratio decay at the tunnel exit. Our open-path NH$_3$ measurements show no delay compared with CO$_2$ in this case. This further supports our conclusion that the surface adsorption time constant for our open-path NH$_3$ measurement is significantly reduced at these measurement timescales compared with previous closed-path sensors.
5 Discussion

The NH$_3$ sensor noise-equivalent limit corresponds to a fractional absorption of $\sim 3 \times 10^{-5}$, comparable (within a factor of 3) with typical, field-deployable laser-based systems (Tittel et al., 2003). The detection limit and precision are limited by electrical noise and optical interference fringing, a dominant noise source in many laser absorption spectroscopy systems (Dharmasi et al., 1998; Werle, 2011). The dominant electrical noise sources are the power supplies used for the detector preamplifier and laser current driver. The dominant interference fringes in our system are due to the back reflections from transmissive optics (laser collimating lens and zinc selenide windows for laser, detector and reference cell packages) and QC laser beam quality for the multi-pass optical cell. Our current efforts focus on improving beam quality of the QC laser high heat load packages and optimizing transmissive optics with custom anti-reflective coatings. We note that the ultimate detection sensitivity is also constrained by other uncertainties, including the ability to isolate spectral interferences from CO$_2$ and O$_3$ absorption features near 9.06 µm when approaching the 100 pptv range.

The 2f signal baseline also affects calibration and zero offset measurements. This baseline is due to a combination of detector nonlinearity, intensity modulation and optical fringing. Further investigations on the long-term stability of this baseline under field conditions will be necessary to characterize the variability of the zero calibration and ultimately improve uncertainties at low mole fractions. This uncertainty is currently the most significant limitation for our open-path NH$_3$ sensor. Signal baseline variability due to temperature changes is of particular concern for open-path systems, where the temperature cannot be controlled due to direct exposure of optical components and power limitations on field platforms.

The laser tuning capabilities also limit the desired sensitivity for open-path detection of the broad NH$_3$ absorption feature. The optimal modulation index for 2f detection ($m = 2.2$ as shown by Reid and Labrie, 1981) cannot be reached with the current QC laser used in our system due to limited current tuning range, which decreases with increasing modulation frequency (Tao et al., 2012a). We can only achieve a modulation index of $\sim 1.4$ for NH$_3$ measurements. To address this issue, the integration of new QC lasers with twice the current tuning range is an ongoing effort.

Despite these limitations, we demonstrate a sensor platform capable of high-sensitivity, high time resolution atmospheric NH$_3$ field measurements. Future autonomous field operation of this sensor for long-term stationary measurements will require further weather-proofing of the prototype sensor for protection from precipitation, dust and insects. These measures are particularly important for the optical cell mirrors, which must be directly exposed to environmental conditions.

6 Summary

We present the instrument performance of a compact, low-power, field-deployable, open-path NH$_3$ sensor. The system uses a QC laser at 9.06 µm, multi-pass Herriott cell, multi-harmonic wavelength modulation spectroscopy and an inline ethylene reference cell. No cryogens are required due to the capabilities of TE-cooled, continuous-wave, distributed-feedback QC lasers and HgCdTe photodetectors. Our open-path NH$_3$ sensor has the requisite capabilities for ground-based atmospheric measurements, with a precision and noise-equivalent limit of 0.15 ppbv NH$_3$ at 10 Hz and total accuracy of 0.20 ppbv NH$_3 \pm 10\%$. The sensor is capable of measuring a large dynamic range of NH$_3$ mixing ratios due to in situ emission sources. The fast (10 Hz) time resolution of the open-path system can be used to capture transient NH$_3$ sources with a short surface adsorption time constant. This is demonstrated by comparing the open-path NH$_3$ sensor response with the simultaneous time response of collocated sensors measuring nonadsorbing species.

It is important to note that surface sampling artifacts in closed-path sensors are typically reduced by minimizing inlet length, optimizing inlet coatings, inlet heating and maintaining high flow rates through small sampling volumes or other special sampling systems (Whitehead et al., 2008; Bianchi et al., 2012). Some of these measures increase power demands and limit portability for a variety of field platforms. In contrast, our open-path approach is advantageous in that it has minimal sampling artifacts and does not require pumps or heaters, allowing for a lower-power, portable design.

The compact, low-power design provides unique capabilities for stationary sensing and mobile platform spatial mapping of NH$_3$ mixing ratios. In addition, the open-path sensor precision, stability and time resolution (10 Hz) make it suitable for future eddy covariance NH$_3$ flux measurements. Future investigations will focus on long-term intercomparisons with existing commercial, atmospheric NH$_3$ sensors and demonstration of open-path eddy covariance NH$_3$ flux measurements. Future measurement applications for this open-path sensor include NH$_3$ emission measurements in agricultural and urban regions to validate emission inventories.
